Abstract

The longitudinal friction acting on a vortex line in superfluid ^4He is investigated within a simple model based on the analogy between such vortex dynamics and that of the quantal Brownian motion of a charged point particle in a uniform magnetic field. The scattering of superfluid quasiparticle excitations by the vortex stems from a translationally invariant interaction potential which, expanded to first order in the vortex velocity operator, gives rise to vortex transitions between nearest Landau levels. The corresponding friction coefficient is shown to be, in the limit of elastic scattering (vanishing cyclotron frequency), equivalent to that arising from the Iordanskii formula. Proposing a simple functional form for the scattering amplitude, with only one adjustable parameter whose value is set in order to get agreement to the Iordanskii result for phonons, an excellent agreement is also found with the values derived from experimental data up to temperatures about 1.5 K. Finite values of the cyclotron frequency arising from recent theories are shown to yield similar results. The incidence of vortex-induced quasiparticle transitions on the friction process is estimated to be, in the roton dominated regime, about 50 % of the value of the friction coefficient, ~ 8 % of which corresponds to roton-phonon transitions and ~ 42 % to roton $R^+ \leftrightarrow R^-$ ones.

I. INTRODUCTION

The dynamics of quantized vortices in helium II constitutes one of the most remarkable topics in the study of superfluidity, but only at absolute zero such dynamics is well understood. At finite temperatures, on the other hand, the motion of vortices is subjected to frictional dissipation arising from the interaction with thermally excited quasiparticles and, while there exists an acceptable empirical knowledge of this phenomenon, the microscopic understanding of it leaves much to be desired, as we shall briefly survey in the following.

At zero temperature the force per unit length acting on a vortex line parallel to the z -axis, moving with a velocity $\mathbf{v}$, is the so-called Magnus force,¹

$$\mathbf{F}_M = \rho_s \kappa \hat{\mathbf{z}} \times (\mathbf{v} - \mathbf{v}_s). \quad (1)$$

Here ρ_s is the superfluid mass density, $\kappa = h/m$ denotes one quantum of circulation (m being the mass of a ^4He atom and h Planck's constant), and $\mathbf{v}_s$ takes into account an eventual uniform superfluid velocity far from the line.

According to the two-fluid model, at nonvanishing temperatures the vortex line moves through a gas of excitations, phonons and rotons, and the friction owing to collisions with such quasiparticles gives rise to a drag force $\mathbf{F}_d$ that must be added to the Magnus force,¹

$$\mathbf{F}_d = -D \hat{\mathbf{z}} \times [\hat{\mathbf{z}} \times (\mathbf{v}_n - \mathbf{v})] + D' \hat{\mathbf{z}} \times (\mathbf{v}_n - \mathbf{v}), \quad (2)$$

where $\mathbf{v}_n$ denotes the normal fluid velocity. It is important to notice that for temperatures above about 1 K, the dragging of normal fluid by the vortex becomes appreciable, and so the normal fluid velocity at the core of the vortex will differ from that measured far from the core.² Consequently, the longitudinal (i.e., parallel to the vortex velocity) and transverse friction coefficients, D and D' , will take different values depending on whether the local or bulk normal fluid velocity is considered in formula (2). In the first case, we refer to such coefficients as the *microscopic* ones, whereas in the second we refer to them as the *phenomenological* ones.³ Different theoretical models have been proposed to account for the transverse coefficient⁴ and a considerable controversy has arisen between them, since the experimental data so far obtained has not been able to provide enough hints to prove their validity. On the other hand, the state of the art is much more satisfactory for the longitudinal coefficient. In the lowest temperature range we begin by mentioning the pioneering study of Rayfield and Reif,⁵ who measured such coefficient for $0.28 \text{ K} < T < 0.7 \text{ K}$ and deduced the value of the roton scattering cross section. The phonon scattering contribution, by contrast, could not be determined because of the scant information arising from the low temperature measurements, where phonons and ^3He impurities strongly compete in the vortex drag force mechanism. Unfortunately, such a situation persists, since no conclusive results on this matter have been reported so far. For temperatures above 0.6 K, however, the phonon and ^3He contributions should be negligible and the drag force is then ascribed to roton scattering. In such a case it was later found that the validity of the Rayfield-Reif results can be extended to higher temperatures up to 1.3 K approximately, with some evidence of a slow increase of the roton scattering cross section value with temperature.⁶

All the above results for temperatures below 1.3 K are based on experiments which measure the drag on large vortex rings.^{5,6} On the other hand, for higher temperatures up to the lambda transition, the value of the friction coefficients is deduced from experiments involving attenuation of second sound in rotating containers that yield measurements of mutual friction on rectilinear vortices.³

The most reliable theoretical study of the phonon drag force seems to be the 1965 Iordanskii's calculation⁷ which confirmed the T^5 temperature dependence of the longitudinal coefficient found previously by Pitaevskii,⁸ except for a correction in the value of the proportionality constant. Actually the Iordanskii formula can in principle be applied to the whole dispersion range, i.e. to any superfluid excitation. His study was based on a model of a weakly interacting Bose gas leading to an expression for the longitudinal coefficient which depends on the quasiparticle-vortex scattering amplitude. While the phonon-vortex scattering amplitude was considered in detail by Iordanskii, in the roton case he made use of a quasiclassical approximation that yielded poor quantitative agreement with the longitudinal friction figures deduced from experiments. It is worth mentioning also, that the Iordanskii

formula has recently been used to model the dissipative dynamics of vortices in trapped Bose-condensed gases.⁹

Within the last decade, there has been several theoretical approaches to the calculation of the longitudinal force, ranging from semiempirical treatments based on numerical simulations of roton-vortex interactions,¹⁰ to more formal results studying the equivalence of adiabatic perturbation and kinetic approaches.¹¹ Some other studies on vortex dynamics in two dimensions were based on the analogy between a quantized vortex in a superfluid and an electron in a uniform magnetic field.^{12,13} Such an analogy stems from the fact that the Lorentz and Magnus forces are both transverse forces whose magnitude is proportional to the velocity. Thus the cyclotron frequency of such vortex motion should be inversely proportional to a vortex effective mass whose value has also been a topic of debate.^{14,15} Moreover, only very recently a quantum theory starting from first principles, which supports the existence of such cyclotron motion, has been proposed showing that there are rotational states of a quantized vortex which form highly degenerate energy levels similar to the Landau levels in the integer quantum Hall effect.¹⁶

The idea of a vortex dynamics ruled by a cyclotron motion is certainly a very simple and appealing one. This led us to begin the study of a quantal Brownian motion model¹⁷ by which the vortex is regarded as a quantum particle coupled to the heat reservoir composed by the quasiparticle (qp) excitations of the superfluid. Thus, it has been shown¹⁸ that the only linear coupling on the vortex degrees of freedom, position and momentum, that leads to a dynamics consistent with the drag force (2), corresponds to the vortex velocity. With respect to the qp dependence of the coupling, we have recently¹⁹ begun to study an interaction Hamiltonian based on the simplest scattering events, consisting in qp-vortex collisions which yield an outgoing qp, making the vortex to raise or lower one Landau level, the latter being equivalent to the above mentioned vortex velocity part of the coupling. In such a preliminary study we focused on temperatures below 0.4 K at which only phonons are thermally excited.²⁰ In the present paper we shall concentrate our attention on the longitudinal friction coefficient, extending our previous approach to include the whole dispersion curve, up to temperatures at which the simple non-interacting qp gas picture is expected to break down ($T < 1.7$ K).

In the next section, starting from a generic translationally invariant vortex-qp interaction potential, we first extract a suitable approximation to first order in the vortex velocity. Then, making use of previous results, the longitudinal friction coefficient is calculated, showing that it turns out to be equivalent to that arising from the Iordanskii formula, in the limit of a vanishing cyclotron frequency. A very simple functional form for the scattering amplitude, which is proposed for the whole qp dispersion range, leads in Section III to a thorough study of the friction coefficient, together with a comparison to the results derived from experiments and an analysis of the incidence of vortex-induced qp transitions of different kinds on the friction process. Finally, a summary and the main conclusions of this study are gathered in Section IV.

II. THE MODEL

To begin with, we note that for a vanishing superfluid velocity, $\mathbf{v}_s = 0$, the Magnus force, Eq. (1), takes the form of a Lorentz force acting upon an electron in a uniform magnetic field. Then classically one has a cyclotron motion dynamics and, quantum mechanically,

an energy spectrum of equally spaced Landau levels,²¹ both pictures ruled by a cyclotron frequency:

$$\Omega = \rho_s \kappa \frac{L}{M}, \quad (3)$$

where L and M respectively denote the vortex length and effective mass. Therefore, the Hamiltonian from which the Magnus force derives can be written as,²¹

$$H_M = \frac{1}{2} M \mathbf{v}^2 = \hbar \Omega \left(a^\dagger a + \frac{1}{2} \right), \quad (4)$$

where

$$\mathbf{v} = \mathbf{p}/M + \frac{\Omega}{2} \hat{\mathbf{z}} \times \mathbf{r} \quad (5)$$

gives the vortex velocity operator in terms of position $\mathbf{r}$ and momentum $\mathbf{p}$ operators, and

$$v_x = i \sqrt{\frac{\hbar \Omega}{2M}} (a^\dagger - a) \quad (6a)$$

$$v_y = \sqrt{\frac{\hbar \Omega}{2M}} (a^\dagger + a) \quad (6b)$$

gives the velocity components in terms of creation ($a^\dagger$) and annihilation (a) operators of right circular quanta. Note that a possible temperature dependence of the cyclotron frequency, arising from the factor ρ_s in Eq. (3), can be avoided by working at low enough temperatures. For instance, the superfluid density ρ_s changes less than 10 % approximately for temperatures below 1.5 K.

The Hamiltonian of the whole system (vortex plus qp gas) is formed by a vortex term Eq. (4), plus a non-interacting qp term, plus an interaction potential term which should take into account the vortex-qp scattering processes. The latter may be modeled through the following translationally invariant form:

$$\sum_{\mathbf{k}, \mathbf{q}} \delta_{k_z q_z} \Lambda_{\mathbf{k}\mathbf{q}} \exp[-i\mathbf{r} \cdot (\mathbf{k} - \mathbf{q})] a_{\mathbf{k}}^\dagger a_{\mathbf{q}}, \quad (7)$$

where $a_{\mathbf{k}}^\dagger$ ($a_{\mathbf{k}}$) denotes the creation (annihilation) operator of a qp of momentum $\hbar\mathbf{k}$, $\Lambda_{\mathbf{k}\mathbf{q}}$ denotes a coupling parameter to be determined, and the Kronecker delta factor assumes that there is no momentum transfer along the vortex line.³ The form (7), however, is difficult to deal with due to the nonlinear dependence on the vortex coordinate. Such a drawback can be overcome by making the replacement,

$$\mathbf{r} \rightarrow \mathbf{r} + \frac{2}{M\Omega} \mathbf{p} \times \hat{\mathbf{z}} = \frac{2}{\Omega} \mathbf{v} \times \hat{\mathbf{z}}$$

in the argument of the exponential in Eq. (7). This modified potential preserves translational invariance and, on the other hand, it makes possible a linear approximation for the usually small values of the vortex velocity, leading to an interaction potential of the form,

$$V = -\mathbf{B} \cdot \mathbf{v} \quad (8a)$$

with,

$$\mathbf{B} = \frac{2i}{\Omega} \hat{\mathbf{z}} \times \sum_{\mathbf{k}, \mathbf{q}} \delta_{k_z q_z} \Lambda_{\mathbf{k}\mathbf{q}} (\mathbf{k} - \mathbf{q}) a_{\mathbf{k}}^\dagger a_{\mathbf{q}}. \quad (8b)$$

It is not difficult to have an estimation of the upper value of the vortex velocity that allows a linear approximation for $\exp[-i\frac{2}{\Omega}\mathbf{v} \times \hat{\mathbf{z}} \cdot (\mathbf{k} - \mathbf{q})]$. Taking $|\mathbf{k} - \mathbf{q}|$ of the order of the roton momentum, and $\Omega \gtrsim 0.01 \text{ ps}^{-1}$ (see Refs. 14 and 16), the argument of the exponential turns out to be less than $v/(25 \text{ cm/s})$. Note that such an approximation yields a zero-th order term, $\sum_{\mathbf{k}, \mathbf{q}} \delta_{k_z q_z} \Lambda_{\mathbf{k}\mathbf{q}} a_{\mathbf{k}}^\dagger a_{\mathbf{q}}$ (cf. Eq. (7)), that should be added to the non-interacting qp Hamiltonian $\sum_{\mathbf{k}} \hbar\omega_k a_{\mathbf{k}}^\dagger a_{\mathbf{k}}$. However, it will be shown later that the coupling parameter $\Lambda_{\mathbf{k}\mathbf{q}}$ turns out to be by far much smaller than the qp energies.

Here it is worthwhile recalling that an interaction potential of the form (8a) (i.e., proportional to the vortex velocity, Eq. (5)), was found to be the only linear combination of vortex position and momentum operators leading to a dynamics in agreement with a drag force of the form (2).¹⁸

It is instructive to identify the scattering processes embodied in the interaction potential (8); in fact if we replace the velocity from Eqs. (6), we find that the interaction consists of terms of the form $a_{\mathbf{k}}^\dagger a_{\mathbf{q}}^\dagger a_{\mathbf{q}}$ and $a_{\mathbf{k}}^\dagger a_{\mathbf{q}}$, i.e. vortex-qp collisions that make the vortex to raise or lower one Landau level.

The quantum mechanical problem posed by the vortex Hamiltonian (4), plus a non-interacting qp Hamiltonian, plus the interaction (8), complemented by a thermal equilibrium assumption for the qp gas, can be solved for the expectation value of the vortex position operator.¹⁹ In fact, making use of the Markov approximation to second order in the coupling parameter, which is assumed to depend only on the modulus of the qp momentum ($\Lambda_{\mathbf{k}\mathbf{q}} = \Lambda(k, q)$), we obtain the following expression for the microscopic friction coefficient,

$$D_\Omega = \frac{2\pi}{\hbar\Omega L} \sum_{\mathbf{k}, \mathbf{q}} \delta_{k_z q_z} |\Lambda(q, k)|^2 (\mathbf{k} - \mathbf{q})^2 [n(\omega_k) - n(\omega_q)] \delta(\omega_q - \omega_k - \Omega), \quad (9)$$

where $n(\omega) = [\exp(\hbar\omega/k_B T) - 1]^{-1}$ denotes the Bose occupation number for the qp excitations. The argument of the above Dirac delta shows the energy conservation rule corresponding to the scattering processes, e.g., a qp of energy $\hbar\omega_k$ combines with a vortex energy quantum, $\hbar\Omega$, to form a qp of energy $\hbar\omega_q = \hbar\omega_k + \hbar\Omega$. Turning in Eq. (9) to the continuum limit according to $\sum_{\mathbf{k}, \mathbf{q}} \delta_{k_z q_z} \rightarrow \frac{L A^2}{(2\pi)^5} \int d^3\mathbf{k} \int d^3\mathbf{q} \delta(k_z - q_z)$, we have,

$$D_\Omega = \frac{A^2}{(2\pi)^4 \hbar\Omega} \int d^3\mathbf{k} \int d^3\mathbf{q} \delta(k_z - q_z) |\Lambda(q, k)|^2 (\mathbf{k} - \mathbf{q})^2 [n(\omega_k) - n(\omega_q)] \delta(\omega_q - \omega_k - \Omega), \quad (10)$$

where A denotes the area of the system in the $x - y$ plane.

We note that within this simple model we are unable to take into account the dragging of normal fluid by the vortex. The qp gas was in fact assumed to remain at rest, which should be a good approximation at least for temperatures up to about 1 K.³

The expression (10), which is the main result of this paper, will be compared to the Iordanskii formula valid for small values of the vortex velocity relative to the qp gas,⁷

$$D_I = - \int \frac{\partial n}{\partial \omega_k} \frac{k_x}{\hbar} \lim_{\rho \rightarrow \infty} \left\{ \int \frac{\delta(\omega_k - \omega_q)}{\delta(k_z - q_z)} (k_x - q_x) |f_\rho(\mathbf{q}, \mathbf{k})|^2 \frac{d^3 \mathbf{q}}{(2\pi)^3} \right\} \frac{d^3 \mathbf{k}}{(2\pi)^3}, \quad (11)$$

where without loss of generality we have assumed a vortex velocity along the x -axis. The scattering amplitude $f_\rho(\mathbf{q}, \mathbf{k})$ corresponds to a vortex-qp interaction potential which is cut off to zero at a distance ρ from the vortex center. Note that the Dirac delta in the denominator of the integrand only makes sense if $f_\rho(\mathbf{q}, \mathbf{k})$ is proportional to $\delta(k_z - q_z)$. At low temperatures only phonon-vortex scattering is relevant, and the limiting process and the integral over the wave vector $\mathbf{q}$ in Eq. (11) commute⁷, so we have,

$$D_I = - \frac{1}{(2\pi)^6 \hbar} \int d^3 \mathbf{k} \int d^3 \mathbf{q} \frac{\partial n}{\partial \omega_k} \delta(\omega_k - \omega_q) k_x (k_x - q_x) \delta(k_z - q_z) |\tilde{f}(\mathbf{q}, \mathbf{k})|^2. \quad (12)$$

The phonon-vortex scattering amplitude $f(\mathbf{q}, \mathbf{k}) \equiv \tilde{f}(\mathbf{q}, \mathbf{k}) \delta(k_z - q_z)$ was extracted by Iordanskii⁷, and its replacement in Eq. (12) yields,

$$D_I = \frac{76}{7} \frac{\zeta(5)(k_B T)^5}{\hbar^2 c_s^7 m^2}, \quad (13)$$

where c_s denotes the sound velocity and $\zeta(n)$ the Riemann zeta function.

Given the difficulties in the calculation of a reliable expression for the scattering amplitude outside the phonon range, we shall assume in what follows that a simplified form like Eq. (12) stands for the whole dispersion range. To compare Eq. (12) with our formula (10), we first note that taking the limit $\Omega \rightarrow 0$ in Eq. (10),

$$D_0 = \lim_{\Omega \rightarrow 0} D_\Omega = - \frac{A^2}{(2\pi)^4 \hbar} \int d^3 \mathbf{k} \int d^3 \mathbf{q} \frac{\partial n}{\partial \omega_k} \delta(\omega_k - \omega_q) (\mathbf{k} - \mathbf{q})^2 \delta(k_z - q_z) |\Lambda(q, k)|^2, \quad (14)$$

an expression very similar to (12) is obtained. Actually, the factor $\delta(\omega_k - \omega_q)$ in Eqs. (11) and (12) corresponds to the common assumption of elastic scattering of qp excitations by a vortex line.^{1,3,5,7,10} On the other hand, a vanishing cyclotron frequency is clearly inadmissible within our model, but if we assume a gap between Landau levels that scales down with the vortex size,^{13,14,16} such a limit may be regarded as a good approximation for a macroscopic system. In fact, Duan¹⁴ based on arguments of gauge-symmetry breaking, proposed for a vortex line in superfluid ^4He an effective mass per unit length logarithmically divergent with the sample size, which for sizes of order ~ 1 cm yields $\Omega \simeq 0.15 \text{ ps}^{-1}$ (Eq. (3)). Arovas and Freire¹³ exploiting the analogy to (2+1)-dimensional electrodynamics, showed that such a divergence is actually cut off at nonzero frequencies, with the wavelength of sound at that frequencies serving as a length scale for the cut-off. Finally, Tang¹⁶ in a quite different approach showed that in two dimensions the level spacing of a vortex increases with the energy and scales down logarithmically with the vortex size. According to his estimation of the gap between the lowest levels, we have $\Omega \simeq 0.011 \text{ ps}^{-1}$ for a vortex in a ^4He superfluid film of size ~ 1 cm. In the next section we shall compare D_0 to D_Ω , with Ω given by the above figures.

Given that the integrand of Eq. (14) is isotropic in the k_x - k_y and q_x - q_y planes, the factor $(\mathbf{k}-\mathbf{q})^2$ can be replaced by $2k_x(k_x-q_x)+2q_x(q_x-k_x)$ and, taking into account the invariance of the rest of the integrand under the replacement $\mathbf{k} \leftrightarrow \mathbf{q}$, both terms can in turn be replaced by $4k_x(k_x-q_x)$. This means that if we identify

$$|\tilde{f}(\mathbf{q}, \mathbf{k})|^2 \equiv (4\pi A)^2 |\Lambda(q, k)|^2, \quad (15)$$

D_I (expression (12)) can be shown to be equivalent to D_0 .

Most of the integration in Eq. (10) can be analytically performed in spherical coordinates, leading to the following one-dimensional integral:

$$D_\Omega = \left(\frac{A}{2\pi}\right)^2 \frac{2}{\hbar\Omega} \int_0^\infty dk k [n(\omega_k) - n(\omega_k + \Omega)] \sum_j \frac{|\Lambda(q_j, k)|^2}{|\omega'_{q_j}|} G(q_j, k) \quad (16a)$$

$$G(q, k) = \begin{cases} kq(q^2 + k^2/3) & (k \leq q) \\ q^2(k^2 + q^2/3) & (q \leq k) \end{cases} \quad (16b)$$

where $\omega'_q = \partial\omega_q/\partial q$ denotes the group velocity arising from the identity

$$\delta(\omega_q - \omega_k - \Omega) = \sum_j \frac{\delta(q - q_j)}{|\omega'_q|}, \quad (17)$$

and the summation runs over the values q_j fulfilling $\omega_{q_j} = \omega_k + \Omega$. Note, however, that the group velocity in the denominator of Eq. (16a) vanishes at the roton and maxon points, and a simple inspection of the integrand of such an equation shows that the only healing to such divergences can stem from the coupling parameter $\Lambda(q, k)$. The simplest form that meets such a requirement is

$$|\Lambda(q, k)|^2 = \alpha |\omega'_q| |\omega'_k|, \quad (18)$$

where the value of the scale parameter $\alpha = (19/560)(2\pi\hbar^2/mAc_s)^2$ was set to reproduce the result (13) from Eq. (16) in the limit of a vanishing cyclotron frequency and the phonon dominated regime ($T \lesssim 0.4$ K). Actually, any power greater than unity of the group velocities in Eq. (18) could avoid the divergencies, but we have found that the first power yields the best fit to the experimental results on D . Note that taking into account in Eq. (18) a highest group velocity of the order of the sound velocity,²² the maximum value of $|\Lambda(q, k)|/\hbar$ turns out to be about $\hbar/mA \sim 10^{-16}$ ps⁻¹ for $A \sim \text{cm}^2$, a value which is by far much smaller than Ω and any characteristic qp frequency (see Fig. 1). Such figures are consistent with the assumption from which Eq. (9) was derived, i.e., a Markov approximation to second order in the coupling parameter. Finally, replacing the form (18) in Eq. (16) and taking the limit $\Omega \rightarrow 0$ we have,

$$D_0 = -\frac{19}{280} \frac{\hbar^3}{m^2 c_s^2} \int_0^\infty dk k |\omega'_k| \frac{\partial n}{\partial \omega_k} \sum_j G(q_j, k), \quad (19)$$

with $G(q, k)$ given in Eq. (16b).

In the next section we shall analyze the above results.

III. RESULTS

Firstly it is expedient to recall our definition of the wave vectors q_j appearing in Eq. (19): given the absolute value of a qp wave vector k and its corresponding energy $\hbar\omega_k$, the equation $\omega_q = \omega_k$ may have one, two, or three solutions in the variable q , which we call q_j ($j = 1, 2, 3$). In fact, (see Fig. 1) for ω_k below the roton minimum there is only one solution, $q_1 = k$, and the same occurs for ω_k above the maxon value. For ω_k lying in between the roton and maxon values there are three solutions, while for ω_k equating any of such values there are two solutions.

The physical meaning of these solutions represents the different possibilities of qp-vortex interaction processes, namely, *pure scattering events* at which the qp momentum is simply deflected conserving its absolute value, or *vortex-induced qp transitions* changing the absolute value of momentum but conserving energy. For instance, a phonon of the highest part of the linear portion of the dispersion curve (e.g., point P in Fig. 1), may undergo three different kinds of interaction with the vortex: (i) a pure scattering event at which the absolute value of momentum is conserved; (ii) a phonon $\rightarrow$ roton R^- transition at which the outgoing qp corresponds to a roton at the left side of the roton minimum²³ (Fig. 1); (iii) a phonon $\rightarrow$ roton R^+ transition. Similarly, an $R^\pm$ roton could be simply scattered conserving the absolute value of its momentum, or could undergo a vortex-induced transition to a phonon or to an $R^\mp$ roton.

The above picture corresponds to the limit of elastic scattering of qp excitations, where the value of the vortex energy quantum (cyclotron frequency) can be neglected with respect to any characteristic qp energy. In fact, as seen from the frequency scale in Fig. 1, values of order $\Omega \simeq 0.01 - 0.1 \text{ ps}^{-1}$ should be expected to be consistent with such a picture, and this assumption will be quantitatively tested later on.

Now it is instructive to plot the integrand of Eq. (19) for different temperatures. In Fig. 2 the panel (a) shows the low temperature behavior, i.e. only the phonon part of the dispersion range is appreciable; while for $T = 0.45 \text{ K}$ (panel (b)) apart from the low temperature phonon peak, there is a couple of minor peaks around the roton minimum ($\sim 1.93 \text{ \AA}^{-1}$) associated to transitions involving $R^\pm$ rotons. There is also a pretty small fourth peak centered around $0.5 \text{ \AA}^{-1}$, which corresponds to phonon $\leftrightarrow$ roton transitions. For $T = 0.6 \text{ K}$ (panel (c)) we observe that both phonon peaks turn out to be of the same order and much smaller than the roton peaks. Finally, for temperatures above 0.9 K only the phonon peak related to transitions is visible, remaining much smaller than the couple of roton peaks (panel (d)).

The above description shows that for temperatures up to 0.4 K , only the phonon part of the dispersion curve is significant in evaluating the expression (19), consequently if we set $q_1 = k$ and $\omega_k = c_s k$ in Eq. (19), we obtain the result (13) as expected. On the other hand, for temperatures above 0.6 K , only the portion of the dispersion curve around the roton minimum makes a significant contribution to the integrand in Eq. (19), then one can safely make use of the usual approximations in roton calculations.²⁴ In fact, the Landau parabolic approximation, $\omega_k = \Delta/\hbar + \hbar(k - k_0)^2/2\mu$, leads to two values for q_j , $q_1 = k$ and $q_2 = 2k_0 - k$; in addition the Bose distribution in Eq. (19) can be well approximated by the Boltzmann distribution, and the range of integration can be extended in such an equation from $-\infty$ to $+\infty$ with negligible error. Under such approximations we have in the roton

dominated regime,

$$D_0 \simeq \frac{38}{105} \frac{\hbar^3 k_0^5}{m^2 c_s^2} e^{-\Delta/k_B T}. \quad (20)$$

Rayfield and Reif⁵ found a similar expression for the temperature dependence of the longitudinal friction coefficient in agreement with their experimental data on large vortex rings obtained for temperatures up to 0.67 K. The validity of such an expression was later⁶ extended to temperatures nearly below 1.3 K. The only difference between our result (20) and the Rayfield-Reif formula stems from the coefficient of the exponential $e^{-\Delta/k_B T}$, which in their case is about 7 % lower than ours. Such a difference, however, turns out to be of the order of the experimental uncertainties. Another common formula in the literature^{2,3} is $D = \rho_n v_G \sigma_{\parallel}$, where $v_G = \langle |\partial \omega_q / \partial q| \rangle = \sqrt{2k_B T / \pi \mu}$ is the average group velocity of thermal rotons, and $\sigma_{\parallel}$ is a longitudinal scattering length which can be approximated by the constant value 8.38 Å for temperatures below 1.3 K. Taking into account the roton approximation for ρ_n , such a formula practically yields the same friction coefficient values as those given by the Rayfield-Reif expression.

Fig. 3 corresponds to plots of the friction coefficient D versus temperature in the range 0.4 K-1.3 K. The circle points were calculated as the sum of the Rayfield-Reif expression plus the Iordanskii expression, Eq. (13); note that above 0.6 K the former clearly dominates giving practically a straight line. The solid line corresponds to D_0 (Eq. (19)), while the values of D_{Ω} with $\Omega = 0.1 \text{ ps}^{-1}$ (Eqs. (16) and (18)) are given by the dash-dotted line, and the corresponding values for $\Omega = 0.01 \text{ ps}^{-1}$ were not plotted since they lie in between the solid line and the center of the circle points in the whole temperature range. From Fig. 3 we may also realize that the expression (20) gives a good approximation to Eq. (19) for temperatures above 0.6 K, where the solid line practically becomes a straight line. But, it is clear that Eq. (20) does not take into account any phonon process or, in other words, we may conclude that the contribution of the phonon peaks in Fig. 2(c-d) must not have an appreciable weight in the integrand of Eq. (19). On the other hand, we have found that the weight of roton $R^+ \leftrightarrow R^-$ transitions is important.¹⁰ In fact, the dashed line in Fig. 3 corresponds to the values extracted from Eq. (19) considering only $q_1 = k$, that is, neglecting both, phonon-roton and roton $R^+ \leftrightarrow R^-$ transitions. Notice that such a curve shows for $T > 0.6 \text{ K}$ the same temperature dependence, $e^{-\Delta/k_B T}$, (i.e., the same slope in Fig. 3) as the expression (20), but the coefficient accompanying the exponential turns out to be substantially minor ($\sim 50\%$).

For temperatures above 1.3 K, the value of the friction coefficient is deduced from experiments involving attenuation of second sound.³ Fig. 4 shows that the microscopic and the phenomenological coefficients become increasingly differentiated above 1.3 K, with important uncertainties for higher temperatures, particularly in the case of the microscopic coefficient. Again we can see that the values for D_0 (solid line) turn out to be slightly greater than those for D_{Ω} with $\Omega = 0.01 \text{ ps}^{-1}$ (dash-double-dotted line), and both keep in excellent agreement with the microscopic values up to temperatures about 1.5 K. The discrepancy observed for higher temperatures could be ascribed to a temperature breakdown of the non-interacting qp gas picture, since the higher experimental values of vortex friction are consistent with an emergence of interaction effects in the qp gas. In addition, possible effects of disregarded dragging of normal fluid by the vortex, and temperature dependence

of Ω , could be affecting our results as well. The effect of neglecting vortex-induced qp transitions is again important, as seen from the dashed line which turns out to be about 50 % lower than D_0 . Most of such transitions are of course between $R^\pm$ rotons since, if we neglect from D_0 in Eq. (19) only phonon-roton transitions, we obtain that the solid curve in Fig. 4 would be decreased less than 8 %.

IV. SUMMARY AND CONCLUSIONS

We have studied the longitudinal friction force acting on a vortex line in superfluid ^4He . Our treatment was based on the analogy between such a vortex dynamics and that of the quantal Brownian motion of a charged point particle in a uniform magnetic field. The friction arising from the scattering of superfluid qp excitations by the vortex was taken into account in the form of a translationally invariant interaction potential which, expanded to first order in the vortex velocity operator, gives rise to vortex transitions between nearest Landau levels. The corresponding friction coefficient was shown to be, in the limit of elastic scattering of qp excitations by the vortex, equivalent to that arising from the Iordanskii formula. To evaluate such a coefficient beyond the phonon dominated regime, we first noticed the singularities in the integrand defining the friction coefficient stemming from the zeros of the qp group velocity (roton and maxon points). Then, from the observation that such divergences could only be avoided given a suitable functional form for the vortex-qp scattering amplitude, a very simple one-parameter form was proposed for the whole qp dispersion range. The unknown scale parameter was adjusted to yield exactly the Iordanskii result for the friction coefficient in the phonon dominated regime, and thus such a coefficient was finally evaluated for higher temperatures taking into account the whole qp dispersion curve.

We have analyzed different possibilities for the calculation of the friction coefficient beyond the phonon range, namely,

- (i) Our expression D_0 , which assumes elastic scattering of qp excitations by the vortex ($\Omega \rightarrow 0$) and yields an excellent agreement with the experimental values up to temperatures about 1.5 K.
- (ii) Our expression D_Ω with cyclotron frequency values extracted from recent theories (Ω ranging between 0.01 and 0.1 ps $^{-1}$), the lower bound of Ω yielding practically the same results as (i) and the upper bound underestimating the experimental data about 20 %.

We have also estimated, in the roton dominated regime, the relative importance of vortex-induced qp transitions on the friction process. We have found that the qp-vortex interaction processes with no change in qp momentum magnitude, are responsible for about 50 % of the value of the friction coefficient, and the remaining contribution arises from roton $R^+ \leftrightarrow R^-$ transitions (~ 42 %) and roton-phonon transitions (~ 8 %).

In conclusion, we have presented a rather simple theoretical model for the longitudinal friction on vortices in helium II, which yields excellent agreement with the values derived from experimental data and provides important insights about the microscopic mechanisms of mutual friction.

FIGURES

FIG. 1. Dispersion curve for elementary excitations in helium II (from Ref. 22). The dotted lines separate the regions where the equation $\omega_q = \omega_k$ changes its number of solutions. The points P , R^- and R^+ on the dashed line illustrate about possible vortex-induced qp transitions.

FIG. 2. Integrand of D_0 (Eq. (19)) for different temperatures. Qualitatively similar plots are obtained for the integrand of D_Ω with Ω of order $0.01 - 0.1 \text{ ps}^{-1}$.

FIG. 3. Friction coefficient D versus temperature. The horizontal and vertical scales are respectively $-T^{-1}$ and $\log_{10} D$. The circle points corresponds to the Rayfield-Reif roton expression (Ref. 5, Eq. (28)) plus the Iordanskii phonon expression (13). The solid and dash-dotted lines correspond respectively to D_0 given by Eq. (19) and to D_Ω with $\Omega = 0.1 \text{ ps}^{-1}$ (Eqs. (16) and (18)). The dashed line corresponds to Eq. (19) without phonon-roton and roton $R^+ \leftrightarrow R^-$ transitions.

FIG. 4. Friction coefficient D versus temperature. The circle points correspond to the values of the microscopic coefficient given in table III of Ref. 3, whereas the square points correspond to the values of the phenomenological coefficient given in table II of the same paper. The dash-double-dotted line corresponds to D_Ω with $\Omega = 0.01 \text{ ps}^{-1}$ (Eqs. (16) and (18)), while the remaining lines are the same as in Fig. 3.
